\textbf{Abstract}

In this paper we present a framework for automated learning within mathematical reasoning systems. In particular, this framework enables proof planning systems to automatically learn new proof methods from well chosen examples of proofs which use a similar reasoning pattern to prove related theorems. Our framework consists of a representation formalism for methods and a machine learning technique which can learn methods using this representation formalism. We present the implementation of this framework within the \textsc{OMEGA} proof planning system – we call our system \textsc{LearnOmega}, and some experiments we ran on this implementation to evaluate the validity of our approach.

\textbf{Keywords:} automated reasoning, theorem proving, proof planning, knowledge acquisition, machine learning
1 Introduction

Proof planning [Bun88] is an approach to theorem proving which uses so-called proof methods rather than low level logical inference rules to find a proof of a theorem at hand. A proof method specifies a general reasoning pattern that can be used in a proof, and typically expands to a number of individual inference rules. For example, an induction strategy can be encoded as a proof method. Proof planners search for a proof plan of a theorem which consists of applications of several methods. An object level logical proof may be generated from a successful proof plan. Proof planning is a powerful technique because it often dramatically reduces the search space, since the search is done on the level of abstract methods rather than on the level of several inference rules that make up a method [Bun00, MS99]. The advantage is that search with methods can be much better structured according to the particular requirements of mathematical domains.

Proof planning also allows reuse of the same proof methods for different proofs, and moreover generates proofs where the reasoning patterns of proofs are transparent, so they may have an intuitive appeal to a human mathematician. Indeed, the communication of proofs amongst mathematicians can be viewed to be on the level of proof plans.

One of the ways to extend the power of a proof planning system is to enlarge the set of available proof methods. This is particularly beneficial when a class of theorems can be proved in a similar way, hence a new proof method can encapsulate the general reasoning pattern of a proof for such theorems. A difficulty in applying a proof pattern to many domains is that in the current proof planning systems new methods have to be implemented and added by the developer of a system. The development and encoding of proof methods by hand, however, is a laborious task. In this work, we show how a system can learn new methods automatically given a number of well chosen examples of related proofs of theorems. This is a significant improvement, since examples (e.g., in the form of classroom example proofs) exist typically in abundance, while the extraction of methods from these examples can be considered as a major bottleneck of the proof planning methodology. In this paper we therefore present a hybrid proof planning system LearnΩMATIC [JKP02b], which uses the existing proof planner ΩMEGA [BCF+97], and combines it with our own machine learning system [JKP02a]. This enhances the ΩMEGA system with an automatic capability to learn new proof methods.

Automatic learning by reasoning systems is a difficult and ambitious problem. Our work demonstrates one way of starting to address this problem, and by doing so, it presents several contributions to the field.

- First, although machine learning techniques have been around for a while, they have been relatively little used in reasoning systems. Making a reasoning system learn proving patterns from examples, much like students learn
to solve problems from examples demonstrated to them by the teacher, is hard. Our work makes an important step in a specialised domain towards a proof planning system that can reason and learn.

- Second, proof methods have complex structures, and are hence very hard to learn by the existing machine learning techniques. We approach this problem by abstracting as much information from the proof method representation as needed, so that the machine learning techniques can tackle it. Later, after the reasoning pattern is learnt, the abstracted information is restored as much as possible.

- Third, unlike in some of the existing related work, we are not aiming to improve ways of directing proof search within a fixed set of primitives [FF98, Sch00] or to patch failed proof plans [Ire92]. In theorem proving systems these primitives are typically inference steps or tactics, and in proof planning systems these primitives are typically proof methods. Rather, we aim to learn the primitives themselves, and to investigate whether this improves the framework and reduces the search space within the proof planning environment. Instead of searching amongst numerous low level proof methods, a proof planner can now search with a newly learnt proof method which encapsulates several of these low level primitive methods.

Figure 1: Approach to learning proof methods.

Fig. 1 gives a structure of our approach to learning proof methods, and hence an outline of the rest of this paper. In Section 2 we examine what needs to be learnt and give some examples of proofs that use a similar reasoning pattern. Then, in Section 3, we present the entire learning process. First, in Section 3.1, we simplify the method representation to ease the learning task. Second, we present our machine learning algorithm in Section 3.2. Third, in Section 3.3 we revisit our method representation and enrich it so that the newly learnt methods
can be used in the \textsc{Omega} proof planner for proofs of other theorems. In order to assess the success of our approach, we go on in Section 4 to present some results of the evaluation tests that we ran on \textsc{LearnOmega}. Finally, we relate our work to that of others in Section 5, and conclude with some future directions in Section 6.

2 Motivation with Examples

A proof method in proof planning basically consists of a triple – preconditions, postconditions and a tactic. A tactic is a program which given that the preconditions are satisfied transforms an expression representing a subgoal in a way that the postconditions are satisfied by the transformed subgoal. If no method on an appropriate level is available in a given planning state, then a number of lower level methods (with inference rules corresponding to the lowest level methods) have to be applied in order to prove a given theorem. It often happens that a pattern of lower level methods is applied time and time again in proofs of different problems. In this case it is sensible and useful to encapsulate this reasoning pattern in a new proof method. Such a higher level proof method based on lower level methods can either be implemented and added to the system by the user or the developer of the system. However, this is a very knowledge intensive task and hence, presents a difficulty in applying a proof strategy to many domains. Hence, we present an alternative, namely a framework in which these methods can be learnt by the system automatically.

The idea is that the system starts with learning simple proof methods. As the database of available proof methods grows, the system can learn more complex proof methods. Inference rules can be treated as methods by assigning to them pre- and postconditions. Thus, from the learning perspective we can have a unified view of inference rules and methods as given sequences of primitives from which the system is learning a pattern. We will refer to all the existing methods available for the construction of proofs as primitive methods. As new methods are learnt from primitive methods, these too become primitive methods from which yet more new methods can be learnt. Clearly, there is a trade-off between the increased search space due to a larger number of methods, and increasingly better directed search possibilities for subproofs covered by the learnt methods. Namely, on the one hand, if there are more methods, then the search space is potentially larger. On the other hand, the organisation of a planning search space can be arranged so that the newly learnt, more complex methods are searched with first. If a learnt method is found to be applicable, then instead of a number of planning steps (that correspond to the lower level methods encapsulated by the learnt method), a proof planner needs to make one step only. On the other hand, if a learnt method is applicable only seldom, then this may have negative effects on some performance criteria of the system (e.g., run time behaviour),
but may not affect others (e.g., even in the worst case, when a learnt method is not applicable, the length of the generated proof plan does not increase, but remains unchanged). Generally, proof plans consisting of higher level methods will be shorter than their corresponding plans that consist of lower level methods. Hence, the search for a complete proof plan can be expected to be performed in a shallower, but also bushier search space. In order to measure this trade-off between the increased search space and better directed search, an empirical study is carried out in Section 4. However, shorter proofs have a general advantage, since they are better suited for a user-adaptive presentation. We discuss this in Section 4.5.

We demonstrate our ideas with examples that we used to develop and test LearnOmega. Most of the example conjectures can be automatically planned for in Omega with the Multi proof planner [MM00]. Throughout this paper, we give a general account of the framework exemplified with the existing implementation. Although some of our examples are trivial and can be proved by the existing proof planning systems, they demonstrate our approach. We remind the reader that our main motivation is not to prove more theorems using the existing machine-oriented reasoners, but to enable proof planners to prove theorems using more human-oriented proof methods. That is, the methods that LearnOmega learns are on a higher level than the existing ones. Hence, the proofs constructed using them are not overwhelmed with unintuitive low-level proof steps, and can be argued to be more intuitive.

2.1 Group theory examples

The proofs of our first set of examples consist of simplifying an expression using a number of primitive simplification methods such as both (left and right) axioms of identity, both axioms of inverse, and the axioms of associativity (where $e$ is the identity element, $i$ is the inverse function, and LHS $\Rightarrow$ RHS stands for rewriting LHS to RHS).

\[
\begin{align*}
(X \circ Y) \circ Z & \Rightarrow X \circ (Y \circ Z) \quad \text{(assoc-r)} \\
X \circ (Y \circ Z) & \Rightarrow (X \circ Y) \circ Z \quad \text{(assoc-l)} \\
e \circ X & \Rightarrow X \quad \text{(id-l)} \\
X \circ e & \Rightarrow X \quad \text{(id-r)} \\
X \circ X^i & \Rightarrow e \quad \text{(inv-r)} \\
X^i \circ X & \Rightarrow e \quad \text{(inv-l)}
\end{align*}
\]

Here are two examples of proof steps which simplify given expressions and the inferences that are used:
\[
\begin{align*}
  a \circ ((a^i \circ c) \circ b) & \quad a^i \circ (a \circ b) \\
  \Downarrow (\text{assoc-l}) & \quad \Downarrow (\text{assoc-l}) \\
  (a \circ (a^i \circ c)) \circ b & \quad (a^i \circ a) \circ b \\
  \Downarrow (\text{assoc-l}) & \quad \Downarrow (\text{inv-l}) \\
  ((a \circ a^i) \circ c) \circ b & \quad e \circ b \\
  \Downarrow (\text{inv-r}) & \quad \Downarrow (\text{id-l}) \\
  (e \circ c) \circ b & \quad b \\
  \Downarrow (\text{id-l}) & \\
  c \circ b & 
\end{align*}
\]

Other examples include proofs for theorems such as \((a \circ (((a^i \circ b) \circ (c \circ d)) \circ f)) = (b \circ (c \circ d)) \circ f\). All of these three examples can be summarised in the following proof traces which are lists of method identifiers:

1. \([\text{assoc-l}, \text{assoc-l}, \text{inv-r}, \text{id-l}]\),
2. \([\text{assoc-l}, \text{inv-l}, \text{id-l}]\),
3. \([\text{assoc-l}, \text{assoc-l}, \text{inv-r}, \text{id-l}]\).

It is clear that all three examples have a similar structure which could be captured in a new simplification method. Informally, one application of such a simplification method could be described as follows:

**Precondition:** There are subterms in the initial term that are inverses of each other, and that are not separated by other subterms, but only by brackets.

**Tactic:**

1. Apply associativity (assoc-l) for as many times as necessary (including 0 times) to bring the subterms which are inverses of each other together, and then
2. apply inverse inference rule (inv-r) or (inv-l) to reduce the expression, and then
3. apply the identity inference rule (id-l).

**Postcondition:** The initial term is reduced, i.e., it consists of fewer subterms.

Note that this is not the most general simplification method, because it does not use methods such as (assoc-r) and (id-r), but it is the one that is the least general generalisation of the given examples above. Note also that the application of this method may fail if the precondition is not strong enough. For instance, two terms
may have to be brought together by the application of the (assoc-r) rule, which
is not covered by the learnt method, since no example of this type has been
provided. Also, should we want our system to learn a recursive application of
this simplification method, then this can be achieved in another round of learning
with suitable examples and methods. Alternatively, our set of initial examples
that the system is learning from needs to include proofs of theorems such as
\((c \circ (b \circ (a^i \circ (a \circ b)))) \circ \(((d \circ a) \circ a^i) \circ f) = c \circ (d \circ f)\) which applies the above
described simplification method three times.

2.2 Residue classes conjectures

There is a large class of residue class theorems in group theory that can be proved
using the same pattern of reasoning. Their use is well documented in [MS01].
Here are examples of three residue class theorems (where \(\mathbb{Z}_i\) is the residue class
of integers modulo \(i\), and the lambda expression is the operation over this set):

1. commutative-under\((\mathbb{Z}_2, (\lambda x, y_\star (x + y)))\)
2. associative-under\((\mathbb{Z}_3, (\lambda x, y_\star (x \times y)))\)
3. commutative-under\((\mathbb{Z}_3, (\lambda x, y_\star (x + y)))\)

The pattern of reasoning to prove them is as follows. First, the definitions (e.g.,
commutative-under, associative-under,) are expanded (defn-exp), and quantifiers
eliminated (\(\forall_i\)-sort). Then, all of the statements on residue classes are rewritten
into corresponding statements on integers by transferring the residue class set
into a set of corresponding integers (convert-resclass-to-num). Then, the proofs
diverge: if the statements are universally quantified, then an exhaustive case analysis
over all elements of the set is carried out (using a combination of elimination
of disjuncts (or-e-rec), simplification (simp-num-exp), and reflexivity (reflex)). If
the statements are existentially quantified, then all elements of the set are ex-
amined until one is found for which the statements hold (using a combination of
disjunction introduction from left or right (ori-r, ori-l), simplification and re-
flexivity; see choose method on page 14). Note that the three example theorems
above are all universally quantified, but the set of theorems used in the evaluation
tests (see Section 4) contains the existentially quantified theorems as well.

The proof trace for the above three theorems consist of a list of method
identifiers used in the proof plans:

1. [defn-exp, \(\forall_i\)-sort, \(\forall_i\)-sort, convert-resclass-to-num, or-e-rec, simp-num-exp,
simp-num-exp, simp-num-exp, simp-num-exp, reflex, reflex, reflex, reflex]
2. [defn-exp, \(\forall_i\)-sort, \(\forall_i\)-sort, \(\forall_i\)-sort, convert-resclass-to-num, or-e-rec, simp-
num-exp, simp-num-exp, simp-num-exp, simp-num-exp, simp-num-exp, simp-num-exp, simp-
num-exp, simp-num-exp, simp-num-exp, simp-num-exp, simp-num-exp, simp-num-exp, simp-

3. [defn-exp, \forall_i-sort, \forall_i-sort, convert-resclass-to-num, defn-exp, or-e-rec, simp-num-exp, simp-num-exp, simp-num-exp, simp-num-exp, simp-num-exp, simp-num-exp, simp-num-exp, reflex, reflex, reflex, reflex, reflex, reflex, reflex, reflex, reflex, reflex, reflex]

2.3 Set theory conjectures

Another problem domain that we experimented with includes some theorems and non-theorems from set theory:

1. \(\forall x, y, z. ((x \cup y) \cap z) = (x \cap z) \cup (y \cap z)\)
2. \(\forall x, y, z. ((x \cup y) \cap z) = (x \cup z) \cap (y \cup z)\)
3. \(\forall x, y, z. ((x \cap y) \cap z) = (x \backslash (y \cup z))\)

Although these problems are not very hard for automated theorem provers if a suitable representation is chosen, they may be hard to prove or disprove for existing automated theorem provers if attempted in a naive way. Their proofs consist of eliminating (introducing, in backwards reasoning) the universal quantifiers (\(\forall_i\)), then applying set extensionality (set-ex) and definition expansions (defni) in order to get propositional or first order clauses (i.e., transforming statements about sets to statements about elements of sets), and then proving (with the Otter theorem prover, atp-otter) or disproving (with the Satchmo model generator, counterex-satchmo) these clauses. Here are the abstracted lists of method identifiers that describe these proofs:

1. \([\forall_i, \forall_i, \forall_i, set-ext, \forall_i, defni, defni, atp-otter]\)
2. \([\forall_i, \forall_i, \forall_i, set-ext, \forall_i, defni, defni, counterex-satchmo]\)
3. \([\forall_i, \forall_i, \forall_i, set-ext, \forall_i, defni, defni, defni, counterex-satchmo]\)

3 Learning

The representation of a problem is of crucial importance for the ability to solve it – a good representation of a problem often renders the search for its solution easy [P45]. The difficulty is in finding a good representation. Our problem is to devise a mechanism for learning methods. Hence, the representation of a method
is important and should make the learning process easy enough that we can learn useful information.

We start by presenting in Section 3.1 a simple representation formalism which abstracts away some detailed information in order to ease the learning process. Then, in Section 3.2 we describe the learning algorithm. Finally, we show in Section 3.3 how the necessary information is restored as much as possible so that the proof planner can use the newly learnt method. Some information may be irrecoverably lost. In this case, extra search in the application of the newly learnt methods will typically be necessary.

3.1 Method outline representation

The methods we aim to learn are complex and are beyond the complexity that can typically be tackled in the field of machine learning. Therefore, we first simplify the problem and aim to learn the so-called method outlines, and second, we reconstruct the full information as far as possible. Method outlines are expressed in the language that we describe here.

Let us define the following language $L$, where $P$ is a set of known identifiers of primitive methods used in a method that is being learnt:

- for any $p \in P$, let $p \in L$,
- for any $l_1, l_2 \in L$, let $[l_1, l_2] \in L$,
- for any $l_1, l_2 \in L$, let $[l_1|l_2] \in L$,
- for any $l \in L$, let $l^* \in L$,
- for any $l \in L$ and $n \in \mathbb{N}$, let $l^n \in L$,
- for $list = (l_1, \ldots, l_k)$ such that $l_i \in L$ and $1 < i \leq k$, let $T(list) \in L$.

“[]” and “|” are auxiliary symbols used to separate subexpressions, “,” denotes a sequence, “|” denotes a disjunction, “*” denotes a repetition of a subexpression any number of times (including 0), $n$ a fixed number of times, and $T$ is a constructor for a branching point ($list$ is a list of branches), i.e., for proofs which are not sequences but branch into a tree. Let the set of primitives $P$ be \{assoc-l, assoc-r, inv-l, inv-r, id-l, id-r\}. Using this language, the tactic of our

\footnote{Note the difference between the disjunction and the tree constructors: for disjunction the proofs covered by the method outline consist of applying either the left or the right disjunct. However, with the tree constructor every proof branches at that particular node to all the branches in the list.

Note also, that there is no need for an empty primitive as it can be encoded with the use of existing language. E.g., let $e$ be an empty primitive and we want to express $[a, b, [e]c], d$. Then an equivalent representation without the empty primitive is $[a, [b][c]], d$. We avoid using the empty primitive as it introduces a large number of unwanted generalisation possibilities.}
simplification method described by the three group theory examples above can be expressed as:

\[
\text{simplify} \equiv [\text{assoc-l}, \text{inv-r}|\text{inv-l}], \text{id-l}].
\]

We refer to expressions in language L which describe compound methods as \textit{method outlines}. \textit{simplify} is a typical method outline that we aim our system to learn automatically.

### 3.2 Machine learning algorithm

Method outlines are abstract methods which have a simple representation that is amenable to learning. We now present an algorithm which can learn method outlines from a set of well chosen examples. The algorithm is based on least general generalisation [Plo69, Plo71], and on the generalisation of the simultaneous compression of well chosen examples.

As with compression algorithms in general, we have to compromise the expressive power of the language used for compression with the time and space efficiency of the compression process. Optimal compression – in the sense of Kolmogorov complexity – can be achieved by using a Turing-complete programming language. This is, however, not computable in general, that is, there is no algorithm which finds the shortest program to represent any particular string. As a compromise we selected regular expressions with explicit exponents and branching points, which seem to offer a framework that is on the one hand, general enough for our purpose, and on the other hand, (augmented with appropriate heuristics) sufficiently efficient.\(^2\)

There are some disadvantages to our technique, mostly related to the run time speed of the algorithm relative to the length of the examples considered for learning. The algorithm can deal with relatively small examples in an optimal way (see Section 3.2.1).

Our learning technique considers some number of positive examples which are represented in terms of lists of identifiers for primitive methods, and generalises them so that the learnt pattern is in language L. The pattern is of smallest size with respect to this defined measure of size, which essentially counts the number of primitives in an expression (where \(l_1, l_2, p \in L, p \in P, n \in \mathbb{N}\) for some finite \(n),\(^2\)

\(2\)Our chosen language \(L\) (see Section 3.1) cannot express all method outlines. For example, we cannot express an outline that a method \(m_1\) (e.g., definition unfolding) should be applied as often as possible, then a different method \(m_2\) should be applied, and finally a third method \(m_3\) (e.g., definition folding) should be applied exactly as often as the first method \(m_1\). In our language we would have to overgeneralise this to \([m_1^*, m_2, m_3^*]\) (unless we know the number of method applications explicitly and this stays the same in all example proofs).
len is length of a list function, and list is a list of expressions from L).

\[
\begin{align*}
    \text{size}([l_1, l_2]) &= \text{size}(l_1) + \text{size}(l_2) \\
    \text{size}(l_1 | l_2) &= \text{size}(l_1) + \text{size}(l_2) \\
    \text{size}(T(\text{list})) &= \sum_{i=1}^{\text{len(list)}} \text{size}(l_i) \text{ where } l_i \in \text{list} \\
    \text{size}(l^*_i) &= \text{size}(l_1) \\
    \text{size}(p) &= 1 \\
    \text{size}(l^*_i) &= \text{size}(l_1)
\end{align*}
\]

This is a heuristic measure of size and the intuition for it is that a good generalisation is one that reduces the sequences of method identifiers to the smallest number of primitives (e.g., \([a^2]\) is better than \([a, a]\)).

The pattern is also most specific (or equivalently, least general) with respect to the definition of specificity \(\text{spec}\) which is measured in terms of the number of nesting for each part of the generalisation.

\[
\begin{align*}
    \text{spec}([l_1, l_2]) &= 1 + \text{spec}(l_1) + \text{spec}(l_2) \\
    \text{spec}(l_1 | l_2) &= 1 + \text{spec}(l_1) + \text{spec}(l_2) \\
    \text{spec}(T(\text{list})) &= 1 + \sum_{i=1}^{\text{len(list)}} \text{spec}(l_i) \text{ where } l_i \in \text{list} \\
    \text{spec}(l^*_i) &= 1 + \text{spec}(l_1) \\
    \text{spec}(p) &= 0 \\
    \text{spec}(l^*_i) &= 1 + \text{spec}(l_1)
\end{align*}
\]

Again, this is a heuristic measure. The intuition for this measure is that we give nested generalisations a priority since they are more specific and hence less likely to over-generalise.

In our experiments, we take both, the size first (choose smallest size), and the specificity second (choose highest specificity) in account when choosing the generalisation. If the generalisations considered have the same rating according to the two measures, then we return all of them. For example, consider two possible generalisations: \([[a^2]^*]\) and \([a^*]\). According to size, \(\text{size}([[a^2]^*]) = 1\) and \(\text{size}([a^*]) = 1\). However, according to specificity, \(\text{spec}([[a^2]^*]) = 2\) and \(\text{spec}([a^*]) = 1\). Hence, the algorithm chooses \([[a^2]^*]\).

Note that there are other ways of selecting a generalisation and find a different compromise between size (keeping learnt expressions small) and specificity (keeping learnt expressions close to the examples). For example, one could vary the value of the following formula \(\alpha \cdot \text{size}(l_i) + (1 - \alpha) \cdot \text{spec}(l_i)\) by changing the value of \(\alpha\) in order to select a suitable generalisation \(l_i\). The value of \(\alpha\) could depend on the degree to which the generalisation should be concise and general/specific (e.g., sometimes it may be beneficial to overgeneralise). Moreover, there are other possible heuristic measures to select a generalisation. We defined and chose size and specificity that are suitable measures in our problem domains.
and with our set of theorems. In the range between specificity and generality, we tend to (slightly) overgeneralise, but the test results in Section 4 demonstrate that our choice is a suitable one.

Here is the learning algorithm. Given some number of examples \( e_i \) (e.g., \( e_1 = [a, a, a, a, b, c] \) and \( e_2 = [a, a, a, b, c] \)):

1. For every example \( e_i \), split it into sublists of all possible lengths plus the rest of the list. We get a list of pattern lists \( pl_i \), each of which contains patterns \( p_k \). E.g.:
   - for \( e_1 \): \( \{[a], [a], [a], [a], [b], [c], [a, a], [a, a, a], [a, b], [c], [a, a, a], [a, a, a, a], [a, a, b], [b, c], \ldots \} \)
   - for \( e_2 \): \( \{[a], [a], [a], [a], [a, a], [a, b], [c], [a, a, a], [a, a, a, a], [a, a, a, a, a], [b, c], \ldots \} \)

2. If there is any branching in the examples, then recursively repeat this algorithm on every element of the list of branches.

3. For every example \( e_i \) and for every pattern list \( pl_i \) find sequential repetitions of the same patterns \( p_k \) in the same example. Using an exponent denoting the number of repetitions, compress them into \( p^c_k \) and hence \( pl^c_i \). E.g.:
   - \( pl^c_1 = \{[a]^4, [b], [c], [[a, a]^2], [b], [c], \ldots \} \)
   - \( pl^c_2 = \{[[a]]^3, [b], [c], [a], [a, a], [b], [c], \ldots \} \)

4. For every compressed pattern \( p^c_k \in pl^c_i \) of every example \( e_i \), compare it with \( p^c_j \) in all other examples \( e_j \), and find matching \( m_k \) with the same constituent pattern, which may occur a different number of times. E.g.:
   - \( m_1 = (pl^c_1, pl^c_2) \) due to \([a]^4\) and \([a]^3\)
   - \( m_2 = (pl^c_1, pl^c_2) \), due to \([b, c]\) and \([b, c]\), etc.

5. If there are no matches \( m_k \) in the previous step, then generalise the examples by joining them disjunctively using the “|” constructor.

6. For every \( p^c_i \) in a matching, generalise different exponents to a “*” constructor, and the same exponents \( n \) to a constant \( n \), and hence obtain \( p_g \). E.g.:
   - for \( m_1 \): \([a]^4\) and \([a]^3\) are generalised to \( p_g = [a]^* \)

\(^3\)Notice that there are \( n \text{ mod } m \) ways of splitting an example of length \( n \) into different sublists of length \( m \). Namely, the sublists of length \( m \) can start in positions \( 1, 2, \ldots, n \text{ mod } m \).

\(^4\)Notice that here is a point where our generalisation technique can over-generalise. For instance, when there is a pattern in the exponents, e.g., all exponents are prime numbers, then this is ignored and just a * is selected.
7. For every \( g \) of a match, transform the rest of the pattern list on the left and on the right of \( g \) back to the example list, and recursively repeat the algorithm on them. E.g.:

- for \( m_1 \) in \( e_1 \): \( \text{LHS} = [\cdot] \), \( g = [a]^* \), repeat on \( \text{RHS} = [b, c] \)
- for \( m_1 \) in \( e_2 \): \( \text{LHS} = [\cdot] \), \( g = [a]^* \), repeat on \( \text{RHS} = [b, c] \)
- for \( m_2 \) in \( e_1 \): repeat on \( \text{LHS} = \{a, a, a\} \), \( g = [b, c] \), \( \text{RHS} = [\cdot] \)
- for \( m_2 \) in \( e_2 \): repeat on \( \text{LHS} = \{a, a\} \), \( g = [b, c] \), \( \text{RHS} = [\cdot] \).

8. If there are more than one generalisations remaining at the end of the recursive steps, then pick the ones with the smallest size and among these the ones with the largest specificity. Else, the examples cannot be generalised. E.g.: for the examples above, not applicable yet; after the algorithm is repeated on the rest of our examples, the learnt method outline will be \([a]^*, [b, c]\).

The learning algorithm is implemented in SML. Its inputs are the sequences of methods identifiers from proofs that were constructed in \( \Omega \text{MEGA} \). Its output are method outlines which are passed back to \( \Omega \text{MEGA} \). The algorithm was tested on several examples of proofs and it successfully produced the required method outlines. In particular, for the examples above:

- Group theory:
  \[
simplify \equiv [\text{assoc-l}^*, [\text{inv-r}\vert\text{inv-l}], \text{id-l}].
  \]

- Residue classes:
  \[
  \text{tryanderror} \equiv [\text{defn-exp}, [\forall_i\,-\text{sort}]^*, \text{convert-resclass-to-num}, \\
  ([\text{or-e-rec}] [\text{defn-exp}, \text{or-e-rec}], \text{simp-num-exp}^*, \text{reflex}^*)]
  \]

- Set theory:
  \[
  \text{learnt-set} \equiv [[\forall_i]^3, \text{set-ext}, \forall_i, \text{defn}^*, [\text{atp-otter}\vert\text{counterex-satchmo}]]
  \]

As mentioned before, the method outline \( simplify \) for the group theory examples is not the most general one, as the examples that it was learnt from did not contain the use of the right identity method, for example. Furthermore, it is only a single application of simplification. However, we tested our learning algorithm also on examples that use this single \( simplify \) method several times. As expected, the learning mechanism learnt a method outline which is a recursive
application of simplify, namely rec-simplify = simplify*. We also tested the learning mechanism on examples that use methods such as right identity and right associativity, and altogether learnt five new method outlines, some of which are recursive applications of others.

In the domain of residue classes, the learning mechanism also learnt another method outline called choose. When fully fleshed into an ΩMEGA method (see Section 3.3), this method proves a subpart of proofs for theorems of residue classes. Namely, given a theorem with an existential quantifier, statements on integers are combined using a disjunction in a particular normal form (from the right side). Then, each disjunct has to be checked until one is found that is true for the statement. Hence, the method choose starts inspecting the right disjuncts until either the right (ori-r) or the left (ori-l) one is true, which is then followed with the rest of the proof, in this case with the application of reflexivity (reflex). This proof pattern is learnt and captured in the method outline:

\[
\text{choose} = [\text{defn-exp, ori-r*, reflex} | [\text{ori-l, reflex}]]
\]

The method corresponding to the third method outline learnt-set, i.e., for set theory examples, transforms a higher-order problem into a propositional logic one, which is much easier to prove or disprove. It does not eliminate search altogether, but makes it, in this case, much more tractable. Notice also, that the method outline learnt-set applies the elimination of the universal quantifier (∀i) only three times. This is consistent with the examples from which the method outline was learnt, but in general the quantifier elimination would be applied any required number of times, which could be denoted with a star construct in the method outline. In general, the quality of a method outline learnt from the examples depends on the quality of the input examples. Hence, it is important to use well chosen examples when learning new methods. Note, however, that sometimes a slight overgeneralisation might be beneficial.

3.2.1 Properties

Let us look at some properties of our learning algorithm:

**Property 1 (Completeness)** The learning algorithm defined above is complete, that is, given a number of examples, the algorithm learns a generalisation which is more general than all examples.

In order to see this property let a language expression \( r \) stand for the set of all expressions that are just sequences of primitive expressions. Then an expression \( r_1 \) is more general than another \( r_2 \) if each primitive expression of the set of sequences for \( r_2 \) is a subset of that for \( r_1 \). In the algorithm only the steps (5) and (6) are critical since all others do not change the generality of the expressions.
Only steps (5) and (6) perform a generalisation, (5) in form of a disjunction, (6) in form of a star. Since a disjunction covers each of its disjuncts, and a star each of its components as well, the property follows.

**Property 2 (Complexity)** *The algorithm which does not make use of heuristics is exponential.*

In terms of computational complexity, the algorithm is quadratic in step (1)$^5$ and is exponential in step (7), since we try every possible combination here. All other steps are linear. The complexity of step (7) could be improved by using the initially computed information about all sublists of an example list, rather than recomputing it in every recursive step.

Since step (7) is exponential, our learning algorithm does not run efficiently for large examples.$^6$ In case the algorithm needs to be used for very large examples, we implemented some heuristic optimisations. These prune the number of generated matches. Good heuristics are those which select matches that make a big impact on the size of the final generalisations. For example, a good heuristic is to pick a pattern match whose pattern of smallest size forms a maximal sublist of the original example. This enables the algorithm to deal with very large examples (e.g., lists of length 2000) which are way beyond the length of examples that we expect for learning our method outlines. Clearly, using such heuristic learning may miss the best generalisation (according to the measures defined above). The user of our LEARNÔMATIC system can choose whether to use the heuristic optimisations in the learning mechanism or not. Users could also define their own heuristics, but this is left for future work.

### 3.3 Using learnt methods

Method outlines that have been learnt so far do not contain all the information which is needed for the proof planner to use them. For instance, they do not specify what the pre- and postconditions of methods are, they also do not specify how the number of loop applications of methods is instantiated when used to prove a theorem. In our approach, we restore the missing information by search.

In the particular case of our implementation in the ÔMEGA proof planning system, important information which is needed for the application of methods – but which is lost in the abstraction process – are parameters for the methods that constitute the newly learnt method. Concretely, the methods which make

---

$^5$An example list of length $n$ is split into all together $n^2$ different sublists: there are $n$ sublists of length 1, $n - 1$ sublists of length 2, $n - 2$ of length 3, $n - k + 1$ of length $k$ and so on, and 1 sublist of length $n$. Hence, in total, there are $n^2$ sublists of different fixed lengths. Notice that there exist algorithms, e.g., suffix trees, which run this step in linear time.

$^6$However, we argue that proof methods that are being learnt typically do not consist of a large number of low level methods. Indeed our algorithm runs efficiently on all the tested examples.
up the new learnt method in ΩMEGA take some (or none) parameters. These
can be in the form of position information indicating where in the expression the
method is applied, or a term naming the concept for which the definition should
be expanded, or instantiating a term used by the method, etc. The parameters
of a method are supplied by control-rules to reduce and to direct the search
performed by the proof planner. For example, the parameter in the definition
expansion method defn-exp names the concept that should be expanded. The
possible relevant control-rules can be of the form ‘Expand only definitions of the
current theory’ or ‘Prefer definition expansion of the head symbol of the formula
to be proved’.

A set of methods together with a set of control-rules defines a planning stra-

gy of ΩMEGA’s multi-strategy proof planner MULTI [MM00]. Note that control-

rules of a strategy are used not only for determining the parameters of methods,
but also to prefer or reject methods according to the current proof situation.

For each learnt method outline we automatically build a method for which
its precondition is fulfilled if there is a sequence of methods that is an executable
instantiation of the method outline. The postcondition introduces the new open
goals and hypotheses resulting from applying the methods of the sequence to the
current goal. We will call this kind of method a learnt method.

The precondition of a learnt method cannot be extracted from the pre- and
postconditions of the uninstantiated methods in the method outline, because the
formulae introduced by the postcondition depend on the formulae that fulfil the
preconditions. We actually have to apply a method to produce a proof situation
for which we can test the preconditions of the subsequent method in the method
outline. That is, we have to perform proof planning guided by the learnt pattern
which is captured by the method outline.

In detail, the applicability test is realised by the following algorithm:

1. Copy the current proof situation. Initialise a stack with a pair \((P_0;\emptyset)\), where
\(P_0\) is the initial learnt method outline and \(\emptyset\) stands for the empty history.

2. Take the first pair from the stack:

(a) If this pair is \([[[P_1;P_2],P'_1];\mathcal{H}]\), then put \([[[P_1,P'_1];\mathcal{H}]\) and \([[P_2,P'_2];\mathcal{H}]\)
back on the stack. For \([[P^n_1,P^n'_1];\mathcal{H}]\) put \([[P,P^{n-1}_1,P'_1];\mathcal{H}]\)
on the stack. In the case of \([[P^*_1,P'_1];\mathcal{H}]\), return \((P^*_1;\mathcal{H})\) and
\([[P,P^*_1],P'_1;\mathcal{H}]\).\footnote{There is a counter for the operator *, the evaluation of this operator is only performed until an upper bound is reached.}

(b) If the pair is \([m,P'_1];\mathcal{H}]\) where \(m\) is a method-name, then test the
precondition of \(m\) for all open goals (and for all possible instantia-
tions of method parameters, if the method contains parameters). Each
satisfied test of preconditions results in a partial matching \(\mu_i\) of \(m\)
for the corresponding goal (and parameter). The partial matchings 
\(([\mu_1, P'], \mathcal{H}), \ldots, ([\mu_n, P'], \mathcal{H})\) are put on the stack. If \(m\) is not
applicable, then backtrack the difference between the current history \(\mathcal{H}\)
and the history of the next pair of the stack.

(c) If the pair is \(([\mu_i, P'] ; \mathcal{H})\) where \(\mu_i\) is a partially instantiated method,
then first apply the postconditions of \(\mu_i\) to the copied proof and then
put \((P', (\mathcal{H}, \mu_i))\) on the stack.

(d) If the pair is \(([] ; \mathcal{H})\) where \([\ ]\) denotes the empty outline, an instanti-
ation of the learnt outline is found, namely, it is the applied methods
stored in \(\mathcal{H}\).

3. If the stack is empty, then it was not possible to apply the learnt method
outline; otherwise continue with step (2).

Notice that the application of the method introduces new open lines and new
hypotheses resulting from the application of methods in \(\mathcal{H}\) into the proof.

The learnt method may contain other learnt methods. That is, the applica-
bility test in (2)(b) may recursively call this same algorithm again within the
applicability test of an embedded learnt method.

Our implementation of the applicability test causes an overhead in the run
time behaviour of the system. This is because the current proof is copied in step
(1) of the applicability test of the learnt method, and also because the new open
goals and hypotheses are copied back into the original proof. These two copying
steps are carried out in order to avoid an interference between the planning
process of \textsc{Multi} in the current proof situation, and the planning process inside
the applicability test of the method outline. The inefficiency due to overhead
could be avoided in a complete re-implementation of the \textsc{Multi} proof planner.

4 Evaluation and Experiments

In order to evaluate our approach, we carried out an empirical study in different
problem domains. In particular, we tested our framework on examples of group
theory, residue classes and set theory. The aim of these experiments was to inves-
tigate if the proof planner \textsc{Omega} enhanced with the learnt methods can perform
better than the standard \textsc{Omega} planner. The learnt methods were added to the
search space in conjunction with a heuristic (control-rule) specifying that their
applicability is checked first, that is, before the existing standard methods.

The measures that we consider are:

1. \textit{matchings} – the number of all true and false attempts to match methods
   that are candidates for application in the proof plan;

2. \textit{proof length} – the number of steps in the proof plan;
3. timing – the time it takes to prove a theorem;

4. coverage – the ability to prove new theorems.

In order to perform these tests we have built different counters in the program. The counter *matchings* counts the successful and unsuccessful application tests of methods. It also contains the method matchings checked by the search engine in the applicability tests of learnt methods (see Section 3.3). *Matchings* provides an important measure, since on the one hand, it indicates how directed the search for a proof is. On the other hand, checking the candidate methods that may be applied in the proof is by far the most expensive part of the proof search. Hence, *matchings* is a good measure to compare the performance of the two approaches (i.e., with and without learnt methods) while it is also independent of potential implementation inefficiencies.

Our evaluation test set includes the theorems from which new methods were learnt, but most of them are new and more complex. Clearly, it is expected that a new method should work for the examples from which it was learnt. This development set usually consists of a small number of examples, in particular, for the examples in the domains discussed in this paper it consisted of three example theorems (see Section 2). The test set consists of the development set plus a number of other theorems that are significantly diverse and of different depth from the development set. We use an informal notion of diversity and depth.

The size of our testing sample was relatively small for group theory: we tested our learnt methods on 11 theorems, but large for other domains: we had 881 theorems of residue classes and 120 conjectures of set theory. Moreover, we chose our testing set to be characteristic of the problem domain in general. Furthermore, notice that some evaluation measures, e.g., *proof length* and *coverage* are independent of the size of the testing set. Namely, some inspection of the approach clearly indicates that the proof plans that use learnt methods will be shorter, and from the domain of group theory, it is clear that new theorems are proved that otherwise could not be.

Table 1 compares the values of *matchings* and *proof length* for the three problem domains. In each problem domain we break down the results according to the type of theorems under consideration (e.g., how complex they are, what pattern of reasoning or proof methods their proofs may use, how many variables are in them). The table compares the values for these measures when the planner searches for the proof with the standard set of available methods (column marked with S), and when in addition to these, there are also our newly learnt methods available to the planner (column marked with L). “—” means that the planner ran out of resources (e.g., four hours of CPU time) and could not find a proof plan.

#### 4.1 Group theory domain

In the group theory domain, our learning mechanism learnt five new methods, but since some are recursive applications of others, we only tested the planner by using two newly learnt complex recursive methods.\(^8\)

The methods simplify group theory expressions by applying associativity left and right methods, and then reduce the expressions by applying appropriate inverse and identity methods (see Section 2.1). The entries in Table 1 refer to two types of examples. First, we give the average figures for simple theorems that can be proved with standard \( \text{and} \) with learnt methods. Second, we give the average figures for complex theorems that can be proved \( \text{only} \) when the planner has our learnt methods.

It is evident from Table 1 that the number of matchings is improved, but it is only reduced by about 15%. We noticed that the simpler the theorem, the smaller the improvement. In fact, for some very simple theorems, a larger number of matchings is required if the learnt methods are available in the search space. The reason for this behaviour is that there are only a few standard methods available initially in the group theory domain. Hence, any additional learnt method will noticeably increase the search space. Also, the application test for learnt methods

\(^8\)In general, it is a good heuristic to keep the size of the set of applicable methods small. This can be achieved by subsuming specialised methods by more general ones. For example, as soon as the system has learnt recursive application of simplify in group theory (\( \text{rec-simplify = simplify}^* \)), we can remove the proof method simplify.
may be expensive, especially when a learnt method is not applicable, but still all possible interpretations of the learnt method outline have to be checked by the search engine. However, for more complex examples, this is no longer the case, and an improvement is noticed. This is because the search within the applicability test of the learnt method is more directed compared to the search performed by the proof planner. The improvement increases when a larger number of primitive methods is replaced by the learnt methods.

As expected, the \textit{proof length} is reduced by using learnt methods.

On average, the \textit{time} it took to prove simple theorems of group theory took approximately 100\% longer than without the learnt methods. Notice that this does not include the case of complex theorems, when the proof planner timed out without finding the proof plans of the given theorems. The reason for bad timing in the case of simple theorems is that the learnt methods are small and simple, and the proof search contains the overhead due to the current implementation for the reuse of the learnt methods (see Section 3.3).

On the other hand, in the case of complex group theory examples, the advantage of having learnt methods in the search space is evident from the fact, that when our learnt methods are not available to the planner, then it cannot prove some complex theorems. When trying to apply methods such as associativity left or right, for which the planner has no control knowledge about their application, then it cannot find a proof plan within the given resources (e.g., four hours of CPU time). Our learnt methods, however, encapsulate typical patterns of reasoning about these theorems, hence they provide control over the way the methods are applied in the proof and lead to successful proof plans.

\section{Residue class domain}

In the domain of residue classes, we gave our learning mechanism examples from the residue class $\mathbb{Z}_3$ domain such that it learnt two new methods: \texttt{tryanderror} (as demonstrated in our examples in Section 3.2), and \texttt{choose}.

We applied the standard set of methods and the set enhanced with the two learnt methods to randomly chosen theorems for the residue class sets $\mathbb{Z}_3$, $\mathbb{Z}_6$ and $\mathbb{Z}_9$. We subdivided the results in Table 1 according to whether only one of the learnt methods or both of them were applicable in the proof.

There is an improvement in each residue class set when learnt methods are available. Since \texttt{choose} replaces only small subproofs, whereas \texttt{tryanderror} can prove the whole theorem in one step, the latter has clearly better results for \textit{proof length} and \textit{matchings}. The benefit in the search for proofs where both learnt methods are applicable lies between them.

In addition to comparing the absolute values for our measures within the different sub-domains of residue class theorems (i.e., $\mathbb{Z}_3$, $\mathbb{Z}_6$ and $\mathbb{Z}_9$) in Table 1, we also compare the relative improvement between the different sub-domains. This can be done by examining the ratio between the number of \textit{matchings} in
Table 2: Ratio between standard and learnt methods.

</tbody>
</table>

the standard (S) and the enhanced (L) sets of methods (and the same for proof length), and then comparing the ratios for each type of theorems across sub-domains. Table 2 states these values.

For example, the ratio for proof length in the case of theorems that use tryanderror method in $\mathbb{Z}_3$ is 19.30. This means that the length of proofs when only standard methods are available is 19.30 times larger than when learnt methods are available as well.

Table 2 clearly shows that the ratios for proof length increase across sub-domains (e.g., in case when both learnt methods are used, the ratio increases from 2.09 to 2.55 and 2.69 across sub-domains). This indicates that the more complex the theorem (higher residue classes have longer and more complex proofs), the better the improvement when learnt methods are available to the planner.

In general, the same trend can be observed for the matchings ratios. An exception are the ratios for the type of theorems that can be proved using tryanderror method, which only marginally decrease across sub-domains (but we would expect them to increase as in the case for theorems that are proved using choose method). This can be explained by the fact that the theorems were randomly chosen across sub-domains, rather than using the theorems for the same properties but different residue classes. Namely, the random differences in the complexity of theorems in different sub-domains may be significant, e.g., the properties randomly chosen in $\mathbb{Z}_6$ may be more complex to prove than the ones chosen in $\mathbb{Z}_3$.

On average, the time it took to prove theorems of residue classes with the newly learnt methods was 50% shorter for proofs containing tryanderror than without such methods, 25% longer for both methods and 80% longer for choose. The time corresponds to the measured matchings but suffers from the overhead of the current implementation, especially for the smaller choose method. Since the learnt methods are tried before the standard set of methods, this effect increases for longer proofs.
4.3 Set theory domain

In set theory the method learnt-set (see Section 3.2) that was learnt from theorems containing three variables was added to the set of available methods. Note that since these theorems have three variables, the universal quantification in learnt-set is eliminated (introduced in backward reasoning) three times.

In order to test whether specialised learnt methods (e.g., for theorems with three variables) can be applied to theorems outside the type they were learnt from, we added to our test set two other types of theorems, namely, with one and with five variables. As expected, learnt-set is not applicable in the proofs of theorems with one variable. In the proofs of theorems with five variables learnt-set is applicable after the standard methods are applied. Note that if we chose ‘better examples’ for learning, e.g., theorems that have one, three and five variables, then our learnt method learnt-set would be more powerful and applicable to all three types of theorems.

For theorems with three variables the proof search performs best, i.e., the number of matchings is reduced by a factor of three when the learnt method is available. proof length is reduced by more than five times. The results for theorems with five variables are still better than without the learnt method, but as expected, not as good as with three variables. For theorems with one variable, where learnt-set is not applicable at all, the proof search clearly suffers from the additionally available learnt method, and hence the number of matchings is increased. proof length is not affected in this case.

The benefits and drawbacks of the availability of learnt methods can be seen very clearly in these evaluation results for the set theory examples. Namely, when a learnt method is applicable, then its availability improves the performance of the proof planner. However, when a learnt method is not applicable then the proof planner has to test a larger set of methods, and this will harm its performance.

On average, the time it took to prove or disprove conjectures in set theory with the newly learnt methods was about 40% faster for theorems with three variables, approximately 5% faster for theorems with five variables, and nearly 20% slower for theorems with one variable.

4.4 Analysis of results

As it is evident from the discussion above, in general, the availability of newly learnt methods that capture general patterns of reasoning improves the performance of the proof planner. In particular, the number of matchings (which are the most expensive part of the proof search) is reduced across domains, as indicated in Table 1. Furthermore, as expected, learnt methods cause proofs to be shorter, since they encapsulate a number of other methods. Also, the time is in general reduced when using learnt methods. There are some overheads, and in some cases these are bigger than the improvements. Since the time should be
related to the reduced number of *matchings*, but it is not in all our cases (group theory), this indicates that our implementation of the execution of learnt methods, as described in Section 3.3, is not as efficient as that of the ΩMEGA proof planner.

In general, the *coverage* when using learnt methods is increased, which is also indicated by the fact that using learnt methods, ΩMEGA can prove theorems that it cannot prove otherwise.

The reason for the improvements described above is due to the fact that our learnt methods provide a structure according to which the existing methods can be applied, and hence they direct search. This structure also gives better explanation why certain methods are best applied in particular combinations. For example, the simplification method for group theory examples indicates how the methods about associativity, inverse and identity should be combined together, rather than applied blindly in any possible combination.

A general performance problem of learnt methods is the behaviour when a learnt method is not applicable. A learnt method is not applicable when there is no instantiation of the learnt sequence so that the methods of this instantiation are applicable. This means that every possible instantiation has to be tested and refuted. In the presented experiments, the learnt methods nearly always outperform the standard set of primitive methods. But there could be worst case scenarios where the learnt method is very general (contains many star operations) and a large part of the learnt sequence is applicable but the whole sequence is not.

### 4.5 Analysis of general approach

The additional hierarchical structure of proofs constructed with learnt methods can also be beneficial for proof verbalisation and proof explanation tools like P.**R**EX [Fie01]. The information hidden within our learnt methods can now likewise be hidden in verbalisations, and expanded if appropriate or requested by the user. Namely, learnt methods encapsulate bigger and more abstract steps in proofs than smaller methods that make up our learnt methods. Hence, learnt methods provide a higher level explanation of what is going on in the proof plan, and therefore they help to reflect the main idea of a proof by masking and grouping details in the proof. When this is combined with proof verbalisation tools, it enables a proof planner to automatically produce better explanations of the proofs which can be as high level or as low level as needed.

The preconditions of learnt methods are currently generated by the search engine for the reuse of methods described in Section 3.3. The engine searches for the instantiation of the method outline which is applicable in a given proof situation. This means that a small amount of search, which is guided by the method outline, needs to be carried out in the applicability test of the learnt method. In the standard set of methods, i.e., not the learnt ones, the applicability test
is carried out by checking if the *explicitly* and *declaratively* stated preconditions for the method hold or not in a given proof situation. No search is carried out within the method. The fact that the preconditions of the standard set of methods are declaratively stated, but the preconditions of our learnt methods need to be computed, does not change how proof methods are treated in the planning process. All methods, whether learnt or not, form part of the search space that the proof planner traverses in the process of finding a proof plan. Indeed, one of our motivations stated at the start of this paper was to devise a mechanism which is able to learn new primitives of the search space, rather than control the search within a fixed set of primitives. In the framework of proof planning the primitives of the search space are proof methods which we can now learn automatically. Even when some search needs to be carried out in order to compute the applicability condition of our learnt methods, this still is much better, that is, search is much pruned, than when such methods are not available to the planner. This is supported by the results of our evaluation demonstrated above in this section.

We can see our approach as a mechanism that learns how to hierarchically structure the search through the search space. We built new methods that encapsulate guided search over some more primitive methods, and then add these new elements as a kind of *chunks of structured search* to our system. This contrasts with the idea of having only one global control layer in proof planning, since our learnt methods themselves can be seen as little planning processes consisting of a set of internal methods and control information on how to search with them.

The mechanism for reusing learnt methods described in Section 3.3 is specific to $\Omega$MEGA proof methods. On the other hand, the learning algorithm presented in Section 3.2 is general and can be used for learning in other automated reasoning systems, not just the $\Omega$MEGA proof planner (see Section 6). The learning algorithm learns method outlines which in other systems could be used as inference rules, in $\Omega$MEGA as proof methods, in $\lambda$Clam [RSG98] as methodical expressions [RS01], etc. In fact, in some systems, like $\lambda$Clam, method outlines are exactly methodical expressions that the planner can use directly, so no enriching of the method outline representation is required. In other systems, method outlines are just inference rules. This may give raise to the question of what is the difference between methods, methodical expressions and tactics. It seems that our method outlines offer a unified view of all these structures that are used in different automated reasoning system, e.g., inferencing systems, tactical theorems provers, and proof planners. Depending on the system, a different primitive of the search space is needed (e.g., inference rules, tactics, proof methods, methodical expressions). Hence, the enriching of the learnt method outline representation so that the new primitive can be used in the given system has to be carried out differently, or may indeed need no enriching at all. Studying how this process varies for different systems may give us some clues about the similarities and differences between such structures, but this is left for future work.
5 Related Work

Some work has been done in the past on applying machine learning techniques to theorem proving. Unfortunately, not much work has concentrated on high level learning of structures of proofs and extending the reasoning primitives within an automated theorem prover.

For example, [Sch00], which is a continuation of previous work such as [FF98, DS96], investigates learning of heuristic control knowledge in the context of machine oriented theorem proving, more precisely, equational or superposition based theorem proving. Knowledge gained from the analysis of the inference process is used to learn important search decisions, which are represented as abstract clause patterns. These are employed in heuristic evaluation functions to better guide the search when attacking new proof problems. The selection of heuristic evaluation functions for a new problem at hand is guided by meta-data. The main difference to our work is that the learnt information in Schulz’s work is not becoming a reasoning primitive, such as our learnt methods. It rather guides the search amongst the existing primitives at the global search layer instead of building up new, structured chunks of encapsulated search processes.

[Sil84] and [Des87] used precondition analysis which learns new inference schemas by evaluating the pre- and postconditions of each inference step used in the proof. A dependency chart between these pre- and postconditions is created, and constitutes the pre- and postconditions of the newly learnt inference schema. These schemas are syntactically complete proof steps, whereas the $\Omega\text{ME\textsc{GA}}$ methods contain arbitrary function calls which cannot be determined by just evaluating the syntax of the inference steps.

Kolbe, Walter, Brauburger, Melis and Whittle have done related work on the use of analogy [MW98] and proof reuse [KW94, KB97]. Their systems require a lot of reasoning with one example to reconstruct the features which can then be used to prove a new example. The reconstruction effort needs to be spent in every new example for which the old proof is to be reused. In contrast, we use several examples to learn a reasoning pattern from them, and then with a simple application, without any reconstruction or additional reasoning, reuse the learnt proof method in any number of relevant theorems.

A piece of related work in cognitive science is Furse’s Mathematics Under- stander [Fur95], MU, which stores mathematical domain and procedural knowledge in a contextual memory system, and tries to simulate how students learn mathematics from textbooks. MU builds up a uniform low-level data structure, while we build high-level hierarchical proof planning methods. Having explicit methods allows us to check proofs for their correctness, while in MU incorrect proof steps cannot be distinguished from correct ones. The hierarchical character of our methods also allows for a user-adaptive proof presentation.

In terms of a learning mechanism, more recent work on learning regular expressions, grammar inference and sequence learning [SG00] is related. Learning
regular expressions is equivalent to learning finite state automata, which are also recognisers for regular grammars. Muggleton has done related work on grammatical inference methods [Mug90] which automatically construct finite-state structures from trace information. His method IM1 is a general one and can describe all other existing grammatical inference methods. IM1 consists of first, generating a prefix tree from example traces, second, merging of states to get canonical acceptor states (which still describe only the example traces), and third, merging states which essentially does the generalisation of the structure. The generalisation, i.e., merging, is determined by a particular chosen heuristic measure. The existing state automata learning techniques differ depending on the heuristic that they employ for generalisation. The main difference to our work is that these techniques typically require a large number of examples in order to make a reliable generalisation, or supervision or an oracle which confirms when new examples are representative of the inferred generalisation. Furthermore, the heuristics described by Muggleton do not seem to be sufficient for generalisation in our case, as none of the states describing our proof traces would be merged. It is unclear what other heuristic could be employed to suffice the generalisation of our examples. Moreover, these techniques learn only sequences, i.e., regular expressions. However, our language is larger than regular grammars as it includes constant repetitions of expressions and expressions represented as trees.

There have been various approaches to incorporate learning in planning. In the PRODIGY system [VCP+95] a number of techniques for learning are available. The goal of the learning process is either to get control knowledge, that is, rules that describe which goal to tackle next and which method to prefer at the decision points of the planning algorithm, or learn planning operators from the change of planning states by observing an expert agent. The learning mechanism of LEARNÔMATIC differs in both aspects as its goal is to learn new operators that are learnt from other operators and could be compared to learning of macro operators of chunks [RLN93]. Another difference is that learning from an analysis of the domain theory, in our case the set of methods, without the generation of examples appears to be difficult, since proof planning methods are complex and the post-conditions are only available when a method is applied in a concrete proof situation. The abstraction from the proof to method names that is the input for the learning mechanism of LEARNÔMATIC is rather radical compared with abstractions in other planning systems, see [Kno92]. There, a hierarchy of abstractions can be established by analysing the predicates of the domain theory. Some ideas for abstractions in method learning that retain possibly useful information are discussed in the next section.

Related is also the work on pattern matching in DNA sequences [Bra94], as in the GENOME project, and some ideas on our learning mechanism have been inspired by this work.

6 Future Work

There are several aspects of our learning framework which need to be addressed in the future. With respect to the representation formalism we have mainly considered sequential rewriting proofs. Other styles (different directions of reasoning) should also be considered.

Furthermore, we would like to apply our learning approach to other proof planners, such as $\lambda Clam$ [RSG98]. Since proof methods have a different structure in different proof planners, this task would require using the same learning mechanism, but probably, instead of our applicability test, a different reuse of methods approach as in the case of $\Omega$MEGA.

The expressiveness of our language $L$ for method outlines (see Section 3.1) could be studied further in order to determine if it should be extended. In particular, we could look into what type of $\Omega$MEGA methods cannot be expressed using the current language $L$, and what other language constructs we would need. Moreover, we could examine if our language is sufficient to express primitives of the search space in other automated reasoning systems, like methodical expressions in $\lambda Clam$ or inference rules in other theorem provers.

Regarding the learning algorithm itself, we need to examine what are good heuristics for our generalisation and how suboptimal solutions can be improved. While the learning mechanism is not efficient, we argue that we do not need a highly complicated and efficient technique for learning patterns, as in the GENOME project, for example. Our algorithm may be simple and naive, but is sufficient for our examples which are typically small (e.g., less than 50 steps).

An interesting aspect that could be addressed in the future is whether a system could automatically learn the information that is abstracted from the proof traces and that has to be reconstructed by search performed in applicability test when reusing learnt methods. What could this additional information that describes learnt methods more specifically be? When we take a look at the examples in group theory, it seems to be obvious that the simplification using associativity, inverse and identity methods are meant to act on the same subformula. This information is lost during abstraction, and hence, during the applicability test of the learnt method, associativity is applied at every possible place. So, the question is, could the smallest subterm of an expression to which the newly learnt method should be applied, i.e., the focus for the method, be learnt automatically and how? Future investigations could address such questions as well as identify additional pieces of information that describe learnt proof methods more specifically.

Another interesting, but difficult idea for future work is to more precisely characterise well chosen examples, so that these could be selected automatically, rather than depend on the user. It would be desirable to identify automatically the subparts of proof traces in several examples of proofs that contain the same reasoning pattern. In our framework, this has to be done by the user of the
system. Techniques from data mining could perhaps be useful to tackle this difficult problem, however, they typically require very large data sets, which in proof planning we typically do not have.

The extraction of method sequences from proofs is currently implemented with respect to the chronological order of method applications during proof planning. There could be other orderings, e.g., the different linearisations of the proof tree, some of them could even result in more adequate learnt method outlines. For example, in a situation where the planner has more than one different subgoal that can be closed by the same sequence of method applications \([m_1, m_2]\), it depends on the search behaviour of the proof planner whether the proofs will have a trace like \([m_1, \ldots, m_1, m_2, \ldots, m_2]\) or \([m_1, m_2, \ldots, m_1, m_2]\). The learning mechanism will produce \([m_1, m_2]^*\) in the first case and \([m_1, m_2]^*\) in the second case. The later will have a better search behaviour in the applicability test of the learnt method because only one instantiation for the star operator has to be found.

In order to model the human learning capability in theorem proving more adequately it would be necessary to model how humans introduce new vocabulary for new (emerging) concepts (e.g., representing associative expressions as lists of terms in the expressions, annotations in rippling \([\text{BSvH}+93, \text{Hut}90]\)). With our approach, we cannot do that, however. It is a very challenging question left for future research.

7 Conclusion

In this paper we described a hybrid system LEARN\ΩMATIC, which is based on the \ΩMEGA proof planning system enhanced by automatic learning of new proof methods. This is an important advance in addressing such a difficult problem, since it makes first steps in the direction of enabling systems to better their own reasoning power. Proof methods can be either engineered or learnt. Engineering is expensive, since every single new method has to be freshly engineered. Hence, it is better to learn, whereby we have a general methodology that enables the system to automatically learn new methods. The hope is that ultimately, as the learning becomes more complex, the system will be able to find better or new proofs of theorems across a number of problem domains.

A demonstration of LEARN\ΩMATIC implementation can be found on the following web page: \texttt{http://www.cs.bham.ac.uk/\textasciitilde mmk/demos/LearnOmatic/}.
